Abstract

Background: Breast cancer is the leading cause of death among women aged 20–59 years worldwide, with 58% of deaths occurring in less-developed countries. In the Islamic Republic of Iran, breast cancer constitutes 21% of all cancers, with an incidence rate of 22 per 100 000 women.

Aims: Since research into breast cancer screening among Iranian women is scarce and results are contradictory, we aimed to explore women’s’ perceptions regarding breast cancer screening behaviour and provide insights into how breast cancer is perceived and approached. This could aid policy-makers in drafting effective interventions to stimulate women to perform regular screening.

Methods: We used the Health Belief Model as a theoretical framework. In-depth interviews with 22 women in Tehran were performed, based on a topic-list exploring the 6 constructs of the Health Belief Model: perceived barriers, perceived severity, perceived susceptibility, perceived benefits, self-efficacy, and cues to action. Data-analysis was based on the Constructivist Grounded Theory Method.

Results: The main barriers were fear, low priority and cultural values. Perceived severity was low for the majority of women, while perceived susceptibility was high for about half of them. Perceived benefit of screening was high for all women. Women’s’ self-efficacy was low when it came to breast self-examination. Talking about breast cancer screening and having somebody in their environment adopting screening behaviour were important cues for taking up breast cancer screening.
Conclusions: Interventions should focus on diminishing barriers and increasing women’s’ self-efficacy and interpersonal communication about breast cancer screening.

Keywords: Iran, breast cancer, breast cancer screening, Health Belief Model.

Introduction

Breast cancer is the leading cause of death among women aged 20–59 years worldwide (1), with 58% of breast cancer-related deaths occurring in less-developed countries (2). In the Islamic Republic of Iran, breast cancer constitutes 21% of all cancers (3,4) with an annual incidence of 22 per 100 000 women (5). Most Iranian women are diagnosed with breast cancer between ages 35 and 44 years (6,7), which is about 10 years younger than their Western counterparts (8). A large proportion of breast cancer is curable if diagnosed in an early stage (9). However, previous studies have shown that many Iranian women are diagnosed with advanced stages of breast cancer when no treatment can be provided, indicating the importance of giving continued attention to early detection (9–11).

To be able to design effective interventions to enhance breast cancer screening behaviour (i.e. breast self-examination (BSE) and clinical breast examinations), insight into the determinants of this behaviour is necessary. However, studies on this topic among Iranian women are scarce and have yielded some contradictory findings. For instance, while some studies showed that Iranian women have adequate knowledge about breast cancer screening methods (12), others indicated the reverse (6,9). Furthermore, some studies found that women with a family history of breast cancer are more likely to go for breast cancer screening (5,13), while others showed that a positive family history did not influence screening behaviour (9,12). Indeed, Rastad, Khanjani and Kalantari found that despite having serious signs of breast cancer, Iranian women might still not be willing to visit a doctor because potential subsequent appointments might cause them to
sacrifice their family responsibility and job commitments (13), a barrier also reported in another study (14). In contrast, Iranian women reported a higher probability of performing BSE if they knew about the benefits, indicating that perceived benefits are positively associated with breast cancer screening behaviour (15). Effective doctor–patient communication and social support might motivate Iranian women to adopt breast cancer screening behaviour too (14).

Given the scarce and contradictory results, this study aimed explore Iranian women’s’ perceptions regarding breast cancer screening behaviour. By conducting a qualitative and theory-based study, additional insights can be gained into how breast cancer is perceived and approached in the Islamic Republic of Iran, which could help policy-makers in drafting effective interventions to stimulate women to perform regular breast cancer screening.

**Methods**

**Participants**

Purposive sampling was used because participants had to fulfil certain characteristics (16). They had to be 30 years or older, the age that Iranian women should start performing breast cancer screening, and willing to be interviewed about breast cancer screening. To achieve a broad spectrum of perceptions, we aimed to recruit a heterogeneous sample comprising women from various sociodemographic backgrounds (e.g. marital status, education level, employment status; see Table 1 for characteristics of the participants). Around half of the participants were recruited via email and telephone using the social network of the first author. Those participants introduced us to the next interviewees, by making use of their own social networks. The number of participants was determined by the principle of data saturation (17), i.e. when no further themes are emerging in addition to existing conceptual categories (18). Data saturation in this study was reached when 22 women living in Tehran had been interviewed. Participants were between 30 and 67 years old and all of them were Muslim.

**Interviews**

Before conducting each interview, an informed consent form explaining the subject of the study and participants’ right to withdraw from the study at any time was read and signed by all participants. Participants were interviewed alone in their chosen location, either at home or at work, in the local language (i.e. Farsi). The interviews lasted around 1 hour and were all audiotaped. All interviews were held during March–June 2016. The study was approved by the ethical committee of the Department of Communication Science, University of Amsterdam.

A topic list was developed based on the constructs of the Health Belief Model (HBM), a model developed to explain why individuals (fail to) participate in health behaviours (19). The HBM has been successfully used in several public health fields, including breast cancer screening (4),
and comprises 6 constructs. The topic list started with some general questions about the participants' background characteristics and a closed question assessing their perception of their general health as good, moderate or bad. This was followed by questions on the 6 general HBM constructs: perceived barriers (e.g. ‘Are there any barriers for you to perform breast cancer screening?’), perceived severity (e.g. ‘How severe do you think breast cancer might be for you?’), perceived susceptibility (e.g. ‘Do you think you are at risk of developing breast cancer?’), perceived benefits (e.g. ‘What do you think the benefits are of having a breast cancer check-up?’), self-efficacy (e.g. ‘Do you think that you are able to check your breasts on your own?’), and cues to action (e.g. ‘Do you talk about having a breast cancer check-up with your husband?’). All questions were followed by open follow-through questions to stimulate participants to reflect on the topic.

Data analysis

The Constructivist Grounded Theory Method was applied to analyse the data (20), using the logic of induction to generate new theory from data in a repetitive and evolving process (21). In this method, emphasis is placed on respondents’ subjective experiences and feelings. All interviews were transcribed and translated into English, and coded in 2 stages. In the first stage, initial coding was applied in which each piece of data was examined line by line to produce as many codes as possible to identify all conceptual possibilities (22). In the second phase, focused coding was applied to group the initial codes under the 6 main categories of the topic list. Hence, the initial codes that referred to 1 of the 6 themes were clustered together and labelled under that theme.

To ensure reliability and validity, 3 transcripts were coded independently by the first and second author. Codings were discussed until mutual agreement was achieved. Subsequently, 2 more transcripts were coded. No differences in coding emerged between the researchers on these 2 transcripts. Consequently, the remainder of transcripts were coded by the first author. In addition, a member check was performed on 9 participants by sending them Farsi versions of the transcriptions to check for accuracy. Only minor changes with regard to the content and transposition of sentences were applied.

Results

Themes

Table 2 shows the definitions of each construct and a summary of the themes which emerged from the interviews using the HBM as theoretical framework.

Perceived barriers

Low priority, fear, cultural values and an inadequate doctor–patient relationship emerged as
main barriers to adopting BSE or clinical breast examinations. All participants reported that they give insufficient priority to taking care of their health and adopting breast cancer screening behaviour. Half of them stated that the well-being of other family members (i.e. husband and children) is of higher priority for them. For example, one of the participants said: “Iranian women put everybody before themselves. They take care of their husband and children first then take care of themselves.”

Fear was identified by the majority of participants to be an important barrier, with fear of knowing that one could be diagnosed with breast cancer being the most frequently mentioned type. To illustrate, one of the participants said: “I have never been to a doctor for breast cancer screening. It scares me a lot. Even finding one lump in my body scares me and I cannot take it. That is why my feet don’t even move to go to a doctor for breast cancer screening.” Fear of knowing that one has breast cancer can be accompanied by fear of the future because of being ill. Uncertainty about the chances of survival and about how to deal with the disease hinders breast cancer screening behaviour. In addition, fear of the reaction of others, such as upsetting others or evoking their pity, was mentioned as a barrier by a few participants. Although these different types of fear prevented participants from adopting breast cancer screening, all stated that they would make themselves overcome their fears and visit a doctor when they feel that something is wrong with their breasts.

Waiting until an illness occurs before going for treatment is an element of a greater barrier related to Iranian cultural values. Most participants supported the value of postponing searching for a solution until something bad (e.g. an illness) happens because they believe that they should live in the moment. Participants associated this “living in the moment” attitude to Iranian culture and the way people are brought up, which leads to a preference for blocking “bad” thoughts. Thinking about illnesses such as breast cancer is an example of a bad thought that should be avoided. Many participants pointed out that they believed that by thinking about bad things, they would cause these bad things to happen. Hence, this caused them to avoid such thoughts. For example, one woman said: “My husband tells me not to think about breast cancer too much, because you know when you think about something it would happen to you”. Hence, the common belief “whatever you think about might happen to you” prevents Iranian women from adopting breast cancer screening behaviour.

Some participants mentioned that an inadequate doctor–patient relationship is a barrier to adopting breast cancer screening. According to them, gynaecologists do not sufficiently encourage women to adopt breast cancer screening. Moreover, the possibility of a wrong diagnosis hinders women’s adoption of breast cancer screening due to the distrust in doctors created. To illustrate, one of the participants said: “My father-in-law was wrongly diagnosed with a disease. We were very worried till it turned out that it was just a wrong diagnosis. That is why I do not trust doctors very much.”
Perceived severity

A small majority believed that breast cancer is not a severe disease because they perceive it to be a curable cancer if diagnosed in an early stage. Five participants considered breast cancer to be a severe disease, but only if one is diagnosed in an advanced stage when no treatment can be provided any more. In addition, there was a third group of 4 women who believed that breast cancer was a severe disease without taking its stage into account. This group attributed having breast cancer with both clinical consequences, such as being in severe pain during treatment, and social consequences, among which were disturbances of everyday life due to having cancer and breast cancer being a threat to feminine beauty, which is posed by the possibility of having to remove the breast(s). As one participant explained: “I think breast cancer is a very severe disease. I associate breast cancer with breast removal. You might survive from cancer, but you have lost your breast and it is not replaceable. Breasts are signs of femininity and beauty for women.”

Perceived susceptibility

Perceived susceptibility was low for about half of the participants due to not having a family history of the disease. They also gave no weight to other factors that could put them at risk for developing breast cancer. Only 2 participants saw themselves at high risk of getting breast cancer due to a positive family history. The other participants, who did not have a positive family history of breast cancer, did see themselves at risk of developing breast cancer because of its high prevalence in the country. They said that due to risk factors such as air pollution, stress and bad diet, it would be illogical to merely consider having a positive family history of breast cancer as a potential risk factor. One of the participants stated: “In my family, I do not have a positive family history of breast cancer. But genetics is one factor. There are other factors such as stress, air pollution and bad diet, which contribute to breast cancer. So, I see myself at risk of developing breast cancer.”

Perceived benefits

Facilitating early detection of breast cancer led to high perceptions of the benefits of screening behaviours by all participants. They believed early diagnosis not only leads to quicker and easier treatment of the disease but also to peace of mind about their health status. One of the participants stated: “One of the benefits of the breast cancer screening is that it makes you relaxed and sure about your health. It gives you peace of mind and you can enjoy your life.”

Self-efficacy

Low self-efficacy was reported by 9 participants with regard to performing BSE. These women indicated that they were not able to distinguish between healthy and unhealthy lumps inside their breasts. In addition, although participants stated that they have the autonomy to make
health-related decisions on their own, the decision-making process can be facilitated by support from their family members. Receiving support and confirmation strengthens their decision to adopt a health behaviour, as the following illustrates: “I decide about my health with the help of my husband. He encourages me to do my check-ups.”

Cues to action

Two themes emerged from the interviews which function as cues to action for breast cancer screening behaviour: talking about breast cancer detection behaviour with family and friends and observing somebody in their environment who has taken up breast cancer examinations. Participants believed that the high prevalence of breast cancer has made it easier for people to talk about the disease compared to a few years earlier. Although 7 participants believed that some people are still not willing to talk about breast cancer due to the negative feelings surrounding it, the majority stated that they talk about breast cancer with family and close friends and that these discussions motivate them to take up breast cancer screening. In addition, seeing somebody in their environment who has taken up breast cancer screening is another cue to action, because observing someone adopting breast cancer screening makes them worried about their own health and motivates them to do the same.

Discussion

Our findings indicate that the most important barriers to adopting breast cancer screening behaviour by Iranian women living in Tehran are fear, low priority and cultural values. Previous studies have also identified fear, in particular fear of knowing that one has breast cancer, as an important factor that hinders breast cancer screening by Iranian women (13,14,23–25). The finding that Iranian women in Tehran prioritize their family above their own health is corroborated by previous studies too (13,14). Our results suggest that giving priority to family members seems to be rooted in the culture and societal expectations in the Islamic Republic of Iran, possibly to the detriment of the women’s own health. However, more quantitative research among different respondents (e.g. women living outside Tehran) is needed to be able to confirm the extent to which this is indeed the case. This study also identified a new barrier, namely the tendency to live in the moment and avoid bad thoughts. Living in a socially, politically and economically unstable country has turned the coping mechanism of living in the moment into a cultural value, upon which Iranians base their everyday behaviour. Thinking about bad incidents is socially rejected and avoiding bad thoughts is promoted as a good way of living. These cultural values are a threat to preventive behaviour, because they replace preventive behaviour with treatment, discouraging Iranian women from preventing illnesses in advance.

The majority of the interviewees did not perceive breast cancer to be a severe disease because they believed that, due to the progression of medical science, breast cancer can be treated more easily than before. Only if breast cancer is diagnosed in advanced stages it is deemed severe by some interviewed women. Only 4 participants, who believed breast cancer to be
severe, considered both the clinical and social consequences of having this disease. Slightly more women in this study perceived themselves to be highly susceptible to the disease, some due to having a positive family history of breast cancer, a finding also reported in previous research (5). Even in the absence of a positive family history though, they find themselves susceptible to breast cancer because of its high current prevalence. In fact, the shared belief among most participants was that a positive family history of breast cancer is no longer the determining factor of the disease as they considered environmental factors, such as air pollution and bad diet, more important risk factors.

Nine participants reported low self-efficacy for BSE. The impact of self-efficacy on performing BSE has been reported in previous research (23) and highlights the importance of implementing educational programmes that teach women how to examine their breasts and become more confident about this detection method. Although the participants in this study reported high self-efficacy with regard to decision-making concerning their health, they admitted that receiving support from family members makes it easier for them to implement their health decisions. In the same vein, talking about breast cancer with family and friends and having somebody in their environment who examines her breasts can serve as powerful cues to action to take up breast cancer screening because this may cause women to become more aware of their own health. Thus, health interventions should motivate women to adopt breast cancer screening by promoting interpersonal communication about the topic.

In conclusion, the findings of this study can assist policy-makers in creating effective health interventions to increase the adoption of breast cancer screening behaviour by Iranian women. Iranian women have positive beliefs about the benefits of breast cancer screening and see themselves as susceptible to the disease, but their screening behaviour is hindered because they give low priority to their health and have deterrent cultural values. Interventions should increase their belief that their own health is equally important as the health of their family members, and should focus on the benefits and importance of preventive behaviour.
