Abstract

Background: University students with heavy smartphone use are vulnerable to smartphone addiction that could be related to depression and trait anxiety.

Aims: To assess gender differences in patterns of smartphone use and addiction in relation to depression and trait anxiety among Saudi university students.

Methods: A cross-sectional study of 1513 students of Taif University, Saudi Arabia. A self-reported questionnaire was used to collect demographic data and data on pattern of smartphone use. The Problematic Use of Mobile Phones (PUMP) scale was used to determine smartphone addiction. The Arabic validated version of the Taylor Manifest Anxiety Scale and Beck Depression Inventory were used to assess trait anxiety and depression, respectively.

Results: A female predominance was found for: prevalence of depression and trait anxiety, PUMP scores, duration of daily mobile use and number of daily calls. A significant positive correlation was found between PUMP score and depression and trait anxiety scores, duration of owning a smartphone, and average duration of each daily call. The PUMP scores were significantly higher in 6th year students, those from the theoretical college, single students, and students who used a smartphone for > 4 hours/day.
Conclusions: Smartphone addiction is a major problem among Saudi university students, and it is associated with depression and trait anxiety. Future studies should aim to establish the best interventions to protect university students from the negative effects of smartphones.

Keywords: addiction, anxiety, depression, smartphone, university students.

Introduction

Smartphones, as well as being telephones, act as internet browsers, social networking facilitators, cameras and multimedia players (1). Overuse of smartphones is associated with adverse effects on daily lives (2), leading to sleep, education, relationship and work problems; stress, loneliness, aggression, hostility and reduced quality of life (3); and adverse effects on physical and mental health (4–6).

Smartphones enable university students to know the latest advances in communications technology, and to make rapid contact with their friends and families (6). College students with heavy smartphone use are vulnerable to smartphone addiction (7–10), which is defined as "the
excessive uncontrolled use of the smartphone despite the awareness of the consequences, with the presence of withdrawal symptoms in any attempt to control" (11). A systematic review has found that severity of depression and anxiety is directly related to smartphone addiction (5), and the same finding has been demonstrated in previous studies of university students (6,9).

According to a study done by United Nations Conference on Trade and Development (UNCTAD), Saudi Arabia ranked first in the world for the highest proportion of mobile phone users (12), with a smartphone distribution rate of 86.1% in 2015 (10). A few recent Saudi studies have addressed smartphone addiction and its psychological adverse effects. One study was done on students of King Saud University, and found a prevalence of smartphone addiction of 48%, with a significant gender differences in the degree of addiction (13). Another study was done in the same university and assessed the adverse physical effects of smartphone addiction on academic performance (14).

Only 2 studies have investigated the relationship between smartphone addiction and depression; 1 on medical students (10), and the other on female high school students (15). Previous researchers have found gender differences in smartphone addiction (6,16). No Saudi study has assessed gender difference, which is vital in planning targeted prevention and intervention strategies to deal with this problem. The aim of the present study was to assess the gender differences in pattern of smartphone use and addiction in relation to depression and trait anxiety among Saudi university students.

Methods

Study design

This was a cross-sectional study of students of Taif University, Taif, Saudi Arabia from November 2017 to March 2018.

Sampling methodology

Multistage sampling was carried out, and the university community of Taif University was the
sampling frame. From the 4 health colleges of Taif University, 1 was chosen by simple random sampling, and the same was done to choose 1 college out of the 7 theoretical colleges, where the male and female sections of each college were included. There were 2138 students registered in both female and male sections of the 2 colleges in the academic year 2017–2018. The response rate was 74.5% and the total number of participants was 1594 students.

Ethical considerations

The study was reviewed and approved by the Research Ethics Committee of Taif University and from the deanships of the chosen colleges. Verbal consent was obtained from the participating students.

Study instrument

A predesigned questionnaire was used with the first few questions on the demographic characteristics, college type and educational grade. In the first section, those who replied yes to ownership of a smartphone were qualified to answer the subsequent sections. Of the 1594 participants, 1570 (98.49%) had a smartphone. Of the 1570 questionnaires, 57 incomplete questionnaires were excluded, leaving 871 valid questionnaires from students of the health college and 642 from the theoretical college. The second section included questions on patterns of smartphone use.

The third section was the Arabic validated version of the Problematic Use of Mobile Phones (PUMP) scale that was used to assess smartphone addiction. The Arabic version of this scale was validated in a previous Saudi study (14), and had excellent internal consistency and convergent validity (18,19). The scale includes 20 questions based on the Diagnostic and Statistical Manual of Mental Disorders (DSM-5) criteria for substance use disorder (17,18), and every question was answered on a Likert scale of 1–5. The total score ranged from 20 to 100, with higher scores indicating more usage and more problematic use.

The fourth section assessed trait anxiety levels using the Arabic validated version of the Taylor Manifest Anxiety Scale that consists of 50 questions. Students’ trait anxiety level was assessed as follows: normal (score of 0–16), mild (17–20), moderate (21–26), severe (27–29), and very severe (30–50) (19).
In the fifth section, depression level was assessed using the Arabic version of the Beck Depression Inventory that includes 21 items. Every item was scored from 0 to 3 according to its severity, and the total score ranged from 0 to 63. The students were assessed as normal if they had a score < 26. Depression level was assessed as follows: mild (26–38), moderate (39–55) and severe (56–63) (20).

Statistical analysis

Data were coded, tabulated and analysed using SPSS version 20 (IBM, Armonk, NY, USA). Qualitative data were expressed as numbers and percentages, and the χ2 test was applied to test the relationship between variables. Quantitative data were expressed as mean (standard deviation), and for nonparametric variables, as median (interquartile range). Mann–Whitney and Kruskal–Wallis tests were applied for comparison between nonparametric variables. Correlation analysis using the Spearman’s test was done, and P < 0.05 was considered statistically significant. As there was no documented cutoff point for PUMP score, we considered the median of our studied group score as a cutoff point. So, the studied group was divided into positive smartphone addiction group (score ≥ 59) and negative smartphone addiction group (score < 59). Binary logistic regression analysis was performed, which analyses independent predictors with odds ratios for a binary outcome (here, smartphone addiction).

Results

The mean age of the participants was 20.58 (1.71) years. Of them, 825 (54.5%) were female and 688 (45.5%) were male, 57.6% were from health colleges, and 10.1% were married (Table 1). Depression and trait anxiety were found in 32.7% and 58.7% of students, respectively (Table 2).

There were gender differences (in favour of females) for: students’ grades, college type, marital status, average duration of daily mobile use, duration of each daily call and number of daily calls (Table 1).
Compared to male students, female students had a significantly higher prevalence of depression (34.9% vs 29.9%) and trait anxiety (69.2% vs 46.1%) respectively (Table 2). The same gender difference was found in relation to depression and trait anxiety scores [median IQR: (18–24 vs 14–22) and (20–9 vs 13–14), respectively]. Female students showed a significantly higher median PUMP value compared to male students (median IQR: 60–27 vs 55–31, respectively).

There were significant positive correlations between PUMP score and depression score ($r = 0.534$, $P < 0.001$), trait anxiety score ($r = 0.225$, $P < 0.001$), duration of owning a smartphone ($r = 0.077$, $P = 0.003$), and average duration of each daily call ($r = 0.189$, $P < 0.001$) respectively.

Median IQR of PUMP score was significantly higher among 6th year students (63–30) compared to other grades ($P < 0.001$), and among students from theoretical colleges compared to health colleges (63–33 vs 53–26) ($P < 0.001$) (Table 3). Single students showed a significantly higher PUMP score compared to married students (60–30 vs 52–24) ($P = 0.008$). The PUMP scores were significantly higher among students who reported average daily smartphone use of $> 4$ hours (median IQR 65–31.25), compared to those who used the smartphone for shorter durations ($P < 0.001$). Students suffering from depression had significantly higher PUMP scores compared to those without depression (median IQR 74–20 vs 48–22) ($P < 0.001$). The same was observed for students who suffered from trait anxiety (median IQR 63–30) compared to those without trait anxiety (51–27) ($P < 0.001$).

Binary logistic regression analysis showed that being female or single, older age, or having depression or trait anxiety were independent predictors for smartphone addiction (Table 4).

Discussion

We found a female predominance for average duration of daily mobile use, average duration of each daily call, and number of daily calls, which agreed with other national and international studies (6,14). Women have been found to be more addictive to social media (14), more interested in social networking (21), and always report a higher number and length of mobile calls (6). This is because women use mobile phones more in social interaction than men do (17).
The prevalence of depression (32.7%) and trait anxiety (58.7%) reported in the present study was in line with that reported recently in Taif University (22, 23). This high prevalence was attributed to academic pressure, stressful college environment, social and cultural factors, and adverse social relationships (24).

In the present study, the mean PUMP score of the whole sample [59.51 (16.93)] agreed with the mean value observed in another Saudi study [60.8 (14.9)] (14). In that study, the mean was an indicator of higher prevalence of smartphone addiction. This is consistent with another Saudi study that revealed a high level of smartphone addiction among high school students (15). The observed mean PUMP score in the present study was comparable to that observed in a study in Pakistan on university students [56.33 (15.92)] (25), and another study of Indian adolescents [59 (1.3)] (26).

The present study showed a significant gender difference according to the PUMP scores in favour of female students, as reported in other studies (6). The gender difference could have resulted from the higher trait anxiety scores among female students, which was positively correlated with PUMP scores. In addition, female students showed more moderate to severe forms of depression (61% vs. 48%) and more severe and very severe trait anxiety (30% vs. 20%) than male students did, and severity of depression and anxiety were correlated with smartphone addiction. Generally, the cause of that gender difference is still not well understood. It could be explained by the significantly higher prevalence of depression among female participants and the known vicious circle between smartphone addiction and depression (27). Some studies have attributed this difference to the extensive female use of smartphones for social purposes compared to men (21,27,28). For more understanding of that gender difference, further research is needed to assess gender-related predictors of smartphone addiction.

In the present study there were significant positive correlations between smartphone addiction and both depression and trait anxiety scores, which has been found in international studies (5,6,9,10) and Saudi studies (15), including 1 in Taif university (5). According to the conclusions from previous studies, smartphone addiction forms a vicious cycle with psychopathology (29). The overuse of mobile phones may increase stress by the continuous checking and response to text messages and notifications (29). This excessive reassurance-seeking behaviour is associated with depression and anxiety (29). Smartphone overuse forces the user to be awake late at night, leading to sleep problems and worsening depression and stress (4). Electromagnetic waves from mobile phones also delay melatonin production and lead to sleep disorders and depression (30). Other studies found that depression is a predictor for mobile phone addiction, as depressed individuals overuse smartphones as a coping mechanism to rid themselves of stress and depressive emotions (31).
In the present study, the 6th year students had significantly higher PUMP scores than students from other years, which is in agreement with another Saudi study (14). However, this is in contrast with other studies that have shown the inverse relationship between age and addictive use of technologies (21). This disagreement could be explained by the older age of our sample of university students who use smartphones for both educational and entertainment purposes, which make them vulnerable to addiction (7–10).

The present study showed that single, compared to married, students had significantly higher PUMP scores. This is in line with other studies in which being single was associated with addictive social networking (13,21). There was a nonsignificant difference between PUMP scores and family monthly income in the present study. This differed from a Malaysian study in which students with higher income had significantly more mobile phone use (32). This variation could be attributed to the different sociocultural factors and socioeconomic standard of Saudi Arabia, which has an oil-based economy (33). This could explain the high and growing rate of smartphone use in Saudi Arabia, which was estimated to be 63.17% in 2016 (34).

Students from the theoretical college showed significantly higher levels of PUMP scores compared to health college students. This could be attributed to the large number of time-consuming tasks of health colleges students who have condensed academic courses, continuous assessments and examinations (22), giving them insufficient time to use smartphones, compared to the theoretical college students. In addition, Saudi medical students are engaged in practical training courses in hospitals as well as studying for the Saudi Medical Licensure Examination (35).

We found significantly higher PUMP scores among students who had an average duration of daily mobile use of > 4 hours, which is consistent with previous studies (7,8,13–15). The significant positive correlation found between PUMP scores and the average duration of each daily call has also been reported in previous studies (7,8).

The younger age of owning a smartphone was significantly associated with smartphone addiction (9). Similarly, we found a significant positive correlation between PUMP scores and duration of owning a smartphone.

In the present study, the risk factors for smartphone addiction were being female or single, older age, or having depression or trait anxiety. This agrees with the results of a wide range of studies done to address this issue (5,6,9,10,13,14,21,27,28). This reinforces the reported gender
One of the limitations of this study was using a self-reported questionnaire that had the possibility of reporting bias. Another limitation was being a cross-sectional study that showed the relation between variables but impeded the detection of the cause–effect relationship. The present study was a single centre study that precludes generalization of the results.

Conclusion

The present study showed that smartphone addiction is a major problem among Saudi university students, and is associated with psychological disorders such as depression and trait anxiety. The study calls for future research on larger numbers of students from other universities to allow the generalization of results. Gender-related predictors of smartphone addiction should be investigated in those studies to explore motivations and contents of smartphone use that lead to that behavioural problem. We recommend raising the awareness of university students about the negative effects of smartphones through health education campaigns, in addition to carrying out counselling campaigns with the help of expert psychotherapists to help smartphone addicts to overcome this problem. These interventions should take in consideration the observed gender difference of the problem.
